On Genetic Information in Cells

Q: If I wanted see the sequencing information of a cell, how would I do it?

A:

- ▶ single cell sequencing
- ▶ bulk RNA extraction
- ▶ spatial transcriptomics

How does ST work?

My Understanding:

How does ST work?

Arrays of spatially barcoded, mRNA capturing, reverse transcription primers.

Each spot has a unique barcode sequence (represented here by different colours)

Each individual spot contains millions of copies of an individual primer

mRNA capture - raw genetic info (mRNA)
Spatial ID "Barcode" - location unique primer
Reverse Transcription Primer - sequence data (in cDNA) incorporating location unique primer so that spatial information is preserved

3 End Goal

Importance Sampling

Given a gene and its expressions in a cell, we could learn its orientation θ and intensity v and choose values that maximize a likelihood (likely Poisson).

Problems with Importance Sampling

- ▶ Only works well with one directional spatial data. e.g. how would this handle...
 - ▶ spatially bimodal data?
 - ▶ alternating patterns?
 - ▶ identical expression everywhere?
- ▶ No direct incorporation of neighbor behavior.

Current Method (enter MoNeT)

MoNeT is a way to perform Gaussian mixture model CNNs in a graph setting.

- ▶ Nodes: Cells
- ▶ Edges: Neighboring Cells
- ▶ Node Attributes: Gene Expression Levels

Image Source: Trimble Inc.

Autoencoder Framework

- ▶ Tissue Sample \rightarrow Low-Dim Representation \rightarrow Recreation of Tissue Sample
- ▶ The low-dimensionality applies to the gene expressions (node attributes) but can also be applied to the size of the graph (number of nodes and edges).
- ▶ Evaluated on Negative Poisson Likelihood Loss

Autoencoder Framework

- ▶ Tissue Sample \rightarrow Low-Dim Representation \rightarrow Recreation of Tissue Sample
- ▶ The low-dimensionality applies to the gene expressions (node attributes) but can also be applied to the size of the graph (number of nodes and edges).
- ▶ Evaluated on Negative Poisson Likelihood Loss

Probabilistic Model (VAE)

The current goal of the project is to create a probabilistic model in the form of a VAE.

This allows us to create a probabilistic model where the latent dimension is easily observable and easily sampled from.

Why does this work matter?

- ▶ Spatial Transcriptomics was invented in 2016, so not much novel deep learning on genetic spatial data has been done yet.
- ▶ Low dimensional data allows us to give some visualization of the spatial genetic data.
- ▶ Graph convolutional networks allow us to *directly* use neighboring cells as relevant information for learning.
- ▶ Once a probabilistic model is built, we want some measurement of the correlation of gene expressions between neighboring cells (and maybe why it is happening).
 - ▶ This leads to an interesting idea of "probabilistically condition on all the things scientists already know about, and see if there's still a strong effect present even after conditioning on everything we know." - Jackson
